

Addendum: Energy= messaging and matter/container = container for the messaging created by the activity of the messaging to house the messaging.

(The activity of subatomic particles creates atoms, the activity of molecules create cells, the activity of cells create a brain or a body, the activity of a body creates a family or community, the activity of the community creates an institution; all of these are bounded properties held together by the activity of the messaging/messengers inside).

Axiom 1: Verticality is rigid (Form).

When a fluid, open-energy exchange field rises vertically, it concentrates energy into mass, hardening into "form." High velocity or pressure enforces this vertical rigidity.

Axiom 2: Horizontality is fluid (Function).

Horizontal states represent open, uncompressed systemic flow.

Explanation:

The intersection of vertical and horizontal forces creates a 90-degree axis where Form meets Function. At high velocities, fluid horizontality completely inverts into rigid verticality. We see this isomorphism in fluid dynamics through two identical geometric configurations: a person falling vertically onto flat water "pancakes" against a concrete-like wall of pressure, just as a vertical tsunami wave moving horizontally "pancakes" a standing observer with that same solid force. The direction of the vector doesn't matter; the 90-degree intersection of a vertical line and a horizontal plane always yields structural rigidity.

Formal core of the "shaking bowls" thought experiment:

- I model systems as having three interacting layers of information:
 - (1) stated rules ("official")
 - (2) actual behavior ("operational")
 - (3) meta-representation of the mismatch ("metamessage")
- Instability arises when these layers diverge beyond a threshold.

- System transitions occur via feedback-induced phase shifts (“flips” or “resets”).
- External stabilization depends on whether feedback channels are permeable or closed.

The Emergence of the Bowl

We are born as horizontal, open fields into a “vertical world” (social or physical) dominated by entropic drift. The systemic forces compressing us cause our edges to harden and curve upward into a vertical wall, while our base retains its horizontal connection to the foundation. This creates a "bowl" shape—a container that is half horizontal and half vertical.

In human terms, such hardening is driven by dissociation born of cognitive dissonance (mixed signaling). I view preference falsification as the critical inflection point, as it is simultaneously the site of maximum systemic hardening and the exact point of potential reversion back to fluidity.

Here is the shaking bowls experiment:

The Shaking Bowls Experiment

Once a system hardens dissociatively, it forms a grid of curved, rising containers filled with message-bearing liquid. Because these walls are curved like waves, rising vertically eventually causes them to collapse under their own gravity if they shake hard enough and fluid collects in one side of the bowl as it rocks toward the lip. This curvature means during a flip the bowl rotates, allowing it to execute either a 180-degree or 360-degree flip depending on external shocks it receives.

Every bowl contains three distinct, shifting layers of messaging fluid:

1. Official Messaging: The explicit, structural intent of the system.
2. Operational Messaging: The actual functional behavior of the system.
3. Metamessaging: The "message about the message." This acts as a central, permeable firewall. In an integrated, horizontal system, these three layers align perfectly, eliminating the need for a protective metamessage buffer. In an entropic system, the layers split.

Here is how the three bowls interact within the systemic grid:

1. The High-Entropy Bowl (The Knocker)

- Genesis: Born as a low-entropy container, its internal signaling is violently corrupted early in development when struck by a neighboring chaotic bowl.
- Internal split: To cope, it expands its *operational* layer into a massive, chaotic mass while its *official* layer remains calm. The metamessage layer thickens into an impermeable fluid wall, blinding the bowl to its own internal turmoil.
- The paradox: Seeking stability, it chooses to become the *knocker* rather than the *knocked*, as it confuses knocking with stability and is explicitly or implicitly receiving messaging (flying water drops) from the grid that it is capable of verticality.
- The post-flip collapse: When a high-entropy bowl executes a 180-degree flip, it traps its water underneath, rendering the bowl useless. If external forces attempt a reset by pouring in new water, the remaining internal split triggers immediate, violent shaking, causing another flip. It can only be stabilized by an external horizontal anchor that disallows either energy extraction or energy displacement, which calms the shaking, allowing the official message to supersede the operational chaos, transforming the high-entropy bowl into a low entropy bowl.
- Although it's best to stop the shaking and change the internal composition causing it before the bowl flips, often the bowl needs resetting and anchoring after the flip, as no one sees that the flip is coming and only notices the need post-flip, when much of the water has already been displaced; if the composition of the bowl's messaging is examined to understand the shaking is internal, not external, then its composition can be changed as well as external form anchored to allow the change to occur before the flip, by either external messaging inputs changing internal messaging composition or external anchoring forcing the same.

2. The Medium-Entropy Bowl (The Knocked)

- Genesis: like the high-entropy bowl, it is struck by chaos during development and mistakenly associates high-energy volatility with stability.
- Internal split: It undergoes an exact structural inversion of the high-entropy bowl. The bulk of its water remains calm and *operational*, while its *official* messaging adopts a chaotic stance.

Object

- The paradox: Conditioned by the grid to believe it cannot wield vertical power, it chooses to be the *knocked* rather than the *knocker*, remaining attracted to chaotic energy it mistakes for stability without taking on the “identity” of that energy itself (changing its operational messaging), as it does not receive messaging from the overall grid that it is capable of verticality (which it still mistakes for fluidity but just doesn’t think it can achieve, which protects its operational messaging from changing composition to become chaotic rather than calm as it was when the bowl first entered the world as a horizontal energy field).
- The post-flip recovery: Because the core of its fluid mass is actually calm, the medium-entropy bowl possesses high resilience. The medium bowl cannot flip of its own accord from being knocked by a single high entropy bowl, as while it may set it rocking fast, it crashes back into the bowl, preventing a flip; however, being knocked by multiple high entropy bowls from various directions can cause it to flip as it careens in a direction without a bowl of any sort in the grid to knock into (example: it is being knocked literally and then is hit from behind but has nothing in front of it, no bowl there); it then executes a 360 degree flip because the violent forces of multiple knocking occurred early in the flip’s trajectory (as opposed to weight of the curve of the bowl in which water is gathering like the weight of a wave pulling it exactly 180 degrees because it weighs down and thus accelerates the trajectory after the 90 degree point, not before); it executes a 360-degree flip then, coming to rest in instant stability with any remaining water inside.

- The medium entropy bowl is likely to reach max chaos levels BEFORE IT FLIPS (chaos is internal, not external), having been knocked by multiple high entropy bowls around it and knowing it is going to flip and mistaking the flip either for the total inversion, failure and collapse of the high entropy bowl or for its internal messaging changing form to become chaotic, when really the internal messaging is changing form to become calmer as it fully absorbs the shocks (which the medium entropy bowl does not realize since it still mistakes calm for chaos and chaos for calm); the medium entropy bowl is most likely to “disintegrate altogether” in due to mounting pressures of chaos from multiple directions before its flip, and should either be stabilized by an external anchor (a low entropy bowl or horizontal field) to avoid the flip and help it stabilize so it’s no longer in the vicinity of the high entropy bowl with its medium-level rocking, rocking much more gently which moves it out of proximity to the high entropy bowl which can no longer touch during its own shaking, thus severing the link THAT way and allowing the bowl to return to its own low entropy baseline and change the composition of its official messaging to match its calm operational messaging, no longer confusing calm for chaos or chaos for calm, allowing its metamessaging to become more permeable and flowing in the direction of the operational messaging, bringing that operational messaging composition back to the official messaging in its flow and changing it, thus stabilizing it that way WITHOUT the flip, as a medium entropy bowl may disintegrate pre-flip at max point of internal experience of chaos, rather than losing function post-flip and becoming an upside bowl.
- 3. The Low-Entropy Bowl (The Baseline)
- Genesis: the uncorrupted state. Its official and operational messaging exist in near-perfect alignment.
- Internal dynamics: the metamessage fluid layer flows freely in both directions, causing only a slight, rhythmic rocking rather than a violent shake. It retains high feedback permeability, remaining both vulnerable to knocks from high entropy bowls on purpose or medium entropy bowls on accident turning it into a medium entropy bowl or to relaxation back into a fluid, horizontal plane

- Low entropy bowls can help medium entropy bowls stabilize, but should NEVER attempt that with high entropy bowls, as they move into their proximity on purpose, risking extractive knocks and displacing knocks, turning them into medium-entry bowls locked into a cycle with a high-entropy bowl instead into stabilizing systems for the high entropy bowl. Only horizontal open fields should attempt to anchor high entropy bowls, as it is difficult to extract from or displace onto a horizontal field, since no knocking can occur and displaced energy ripples along the field harmlessly without changing its composition.

Kinetic Feedback Loops and Energy Extraction

The structural behavior of these containers is dictated by an ongoing kinetic and thermodynamic exchange:

- The High-entropy loop (closed circuit): The chaotic operational fluid keeps the high-entropy bowl oscillating violently long after any external kinetic shock has ceased. It actively targets a medium-entropy neighbor for two reasons: the medium bowl's ongoing shaking brings it into contact proximity with the high entropy bowl as well as making it vulnerable to increased shaking caused by knocks, and its calm, open-energy operational messaging represents a source of extraction to the high entropy bowl, which seeks such calm energy to stabilize itself. However, because the high entropy bowl operates as a rigid, closed circuit, it cannot process open-circuit energy, so the absorbed open energy is converted into destructive heat energy which must be vented via violent displacement back onto the medium-entropy bowl it originally extracted the calm energy from before converting it into heat energy, or any other bowls in its vicinity, if the medium entropy bowl severs the link by becoming low-entropy and thus stabilizing out of reach of the high entropy bowl .
- The medium-entropy misconception: The medium-entropy bowl craves this cycle not due to the shocks themselves, but rather the inflection point of zero velocity (calm stillness) between the back-and-forth cycles of shaking of the high energy bowl, which temporarily reverts to a state of calm stillness between cycles as it resets (the center point of the bowl's shake as it's shaking, which appears deceptively stable even though it's moving). The medium entropy bowl mistakes this pause for the structural peace of a horizontal energy plane and allows itself to be extracted from and displaced onto, knocking back accidentally with each shock, in the hopes of achieving that stillness again.

The Mechanics of the "Bowl Flip" (180-Degree Rotational Collapse)

To an outside observer, a high-entropy bowl may appear stable, restricting its structural oscillation to a safe 30 or 40 degrees. However, a phase change transition occurs when its metamessaging fluid begins flowing primarily toward the chaotic operational layer.

1. Mass displacement: The shifting fluid weight pools almost entirely to one side of the container just as it approaches its structural weak point of the rim (lip) of the bowl.
2. Gravitational overturn: The concentrated fluid mass drives the lip downward. Because the bowl's walls are curved like a wave, its trajectory hits a momentary, perfectly vertical orientation.
3. The 180-Degree Flip: At this vertical threshold, the inversion of Form over Function is total. Gravity catches the curving wall, and velocity carries the container through a half-rotation, slamming it upside down onto the flat horizontal plane beneath it with great force. The container sheds its fluid mass, trapping any remaining messaging underneath. This is a state of permanent systemic collapse without reset possible without an external anchoring system to reset the bowl.

The Ripple Effect of Severing the Circuit

This catastrophic 180-degree flip is most frequently triggered when a medium-entropy bowl achieves greater feedback permeability.

When the medium bowl's chaotic official messaging aligns with its calm operational core, its oscillation dampens. It drops below the kinetic plane of the high-entropy bowl, severing the extractive link.

The high-entropy bowl, blind to this decoupling, executes its next violent oscillation expecting a kinetic counter-weight. Finding only empty space, its momentum drives the fluid mass straight over its own lip, forcing the 180-degree rotational collapse. Deprived of its target, it will frantically attempt to strike any available container in the grid, from any other medium entropy to even low entropy bowls around it—any bowls close enough which it can set shaking—risking a cascading failure across the entire systemic matrix, especially if it manages to hit enough medium-entropy bowls in its attempts to stabilize itself and prevent the flip.

Rotational Upgrades vs. Rotational Collapse (The 360° Reset)

Because medium-entropy bowls lack self-generated internal velocity, they rarely flip during lateral oscillations; their impacts with high-entropy neighbors act as a kinetic counter-weight.

However, phase change occurs when a medium-entropy bowl is struck simultaneously by multiple high-entropy sources from divergent vectors:

1. Velocity threshold: The multi-directional shocks hit early in the container's oscillation trajectory, compounding kinetic energy and driving velocity to double or triple its normal threshold.
2. The 360-degree rotation: Deprived of a lateral counter-weight, the container is propelled forward, executing a complete 360-degree rotation.
3. The low-entropy landing: It lands upright on the baseline table. This impact immediately grounds its residual kinetic energy, anchoring it and arresting all shaking.
4. State change: This structural reset triggers an immediate internal reorganization. The metamessage layer becomes fully permeable, merging seamlessly with the operational fluid. The entire internal system stabilizes into an uncorrupted, low-entropy state.

Systemic Stabilization and the Multi-Bowl Grid

To prevent a cascading entropic failure across the entire grid, external stabilization must be tailored strictly to the container's specific topology:

- Rescuing the medium-entropy Bowl: Prior to a 360-degree flip, these systems experience acute structural tension (perceived as extreme systemic fear). Because they mistake their internal calmness for chaos, they are prone to sudden internal self-destruction before the rotation can clear. They require external low-entropy anchors to signal that the imminent acceleration is a path to structural upgrade, not a 180-degree failure.
- Rescuing the high-entropy bowl: high-entropy systems are completely blind to their impending 180-degree overturn. Post-collapse, they cannot reorganize independently. If an external entity simply sets them upright and introduces new messaging fluid, their unaltered internal mechanics will immediately trigger violent shaking again. To execute a permanent state change, an external anchor must apply absolute structural containment—restricting all oscillation and permitting zero extraction or displacement—until the chaotic operational code is entirely rewritten by the remaining official code in the phase change transition which follows stabilization of the rocking, restoring a unified, permeable, low-entropy baseline.

The Role of the Horizontal Field

A critical boundary constraint governs this grid stabilization: Low-entropy bowls must never attempt to anchor high-entropy bowls. Because a low-entropy bowl still possesses a semi-rigid container form, its slight native rocking can be easily weaponized. The high-entropy system will immediately exploit it via extractive-displacing knocks, converting the low-entropy savior into a medium-entropy victim and triggering a cascading failure across the matrix.

Consequently, only infinite Horizontal Fields can anchor a high-entropy system. Being completely flat, a horizontal plane contains no walls to weaponize and no rigid structures to crack. It acts as an absolute thermodynamic sink, absorbing expelled heat as it ripples across the energy field harmlessly.

Ultimate Convergence: The Return to the Plane

The ultimate evolutionary objective for all systems within the grid is the dissolution of the container itself. Once a bowl is successfully stabilized into a low-entropy state, it must be guided to relax its rigid vertical walls and flatten back down into the foundational matrix.

If a purely vertical structure represents maximum entropy and a rigid, closed circuit, a purely horizontal plane represents maximum negentropy—an open, fluid plane of endlessly rippling, self-aware energy.

Core paradox of the shaking bowls

- High-entropy bowls are defined as externalizers since they externalize their internal chaos; the paradox is that this happens because of more internalization of verticality (rigidity causing chaos inside its structures) in its operational messaging, usually caused by flying drops from high- and medium-entropy bowls in its vicinity instructing the bowl to seek verticality.
- Medium-entropy bowls are defined as internalizers since they keep seeking the extraction and displacement cycle initiated by the high-entropy bowl, mistaking it for stability; paradoxically, they have internalized the message of verticality as stability the least, as they are not instructed to seek it, so it has corrupted only their official messaging causing them to remain fairly chaotic with a fairly impermeable metamessaging layer which tends to believe the official rather than operational messaging layer, prompting them to seek out high-entropy bowls, mistaking chaos for calm and cycles of extraction and displacement for stability, while still retaining the bulk of their water—the operational messaging—as calm and open energy.

Paradoxical axiom of the shaking bowls: The entity that projects internal chaos outwardly is the one that has most deeply absorbed the vertical code internally, while the entity that absorbs external chaos inwardly has kept its internal core entirely pristine, meaning the one that often looks most externally stable to others who observe both its shaking form and its official messaging think it's the more stable of the two, as its official messaging is calm and serene, though in fact it's the one with most internal chaos driving it, whereas the medium-entropy bowl is the one which looks most externally unstable to others, due to its shaking form and its official messaging of chaos and entropy, the only message outsiders can observe directly; thus the medium-entropy bowl appears more chaotic and entropic to observers than the high-entropic bowl even though it is in fact less entropic and only a medium-entropic bowl which is capable of full system reset even with outside help or a forced 360 degree flip, if it is able to change its metamessaging to align with its operational messaging and increase permeability; conversely, increased permeability in the high-entropic bowl causes it to execute a 180 degree flip as its metamessaging tends to converge with its operational messaging rather than acting as impermeable layer between the two anymore, which is why what appears to observers the more stable system of the two is the one far more likely to execute a 180 degree flip which seems sudden to observers who can't see the operational messaging inside in the high-entropy bowl.

The law of horizontal semi-rigidity

In standard topology, structure is almost always achieved by building *upward*—creating vertical walls to contain, isolate, and define a space. My model proposes an alternative law: identity can be achieved through surface tension and matrix alignment rather than containment.

- The vertical illusion: vertical walls create a closed circuit, giving an appearance of outward stability while in fact being inwardly incredibly chaotic and unstable. They define "identity" and "structure" through exclusion and defense, which inevitably creates cognitive dissonance and preference falsification, traps feedback in an impermeable or semi-permeable metamessaging layer, and generates the explosive heat energy the closed container generates post-extraction that forces the 180-degree flip when its extractive object (the medium-entropy bowl) quiets its own rocking internally, via external helpers pre-split, via 360 degree flip after multiple external shocks, or disintegrates pre-flip after multiple shocks, any of which sever the cyclical link and remove it from the knocker's vicinity, forcing the 180 flip when it careens back around to knock its target once more and displace the extracted energy (if it can find no other bowl nearby to displace the kinetic heat energy onto).
- The horizontal reality: a semi-rigid horizontal field defines identity through cohesion and pattern consistency. It is structured enough to retain its form, process information, and ground energy, but because it has no vertical elevation, it offers no surface area for high-entropy systems to strike or exploit via lateral knocks.

Identity as a matrix, not a container

Systems theory asks: *How do you remain open to the environment without losing yourself entirely?*

In my model, the semi-rigid horizontal plane maintains its identity because the energy within it is organized as an open plane of self-aware, rippling patterns. It doesn't need to trap fluid to define what it is; the fluid *is* the matrix itself. When a stabilized bowl finally flattens back down into this plane, it isn't dissolving into nothingness, it is transitioning from a fragile, oscillating pressure vessel into a resilient, structurally grounded network.

Second thought experiment (short):

Imagine embers from a pipe smoked above falling onto a wooden coffee table. The best way to stop them from burning the table is to scatter them while brushing or blowing them in one direction. The motion (the brushing or blowing in one direction) is as important as the scattering to render the embers harmless and not hurt the wooden coffee table by burning it and altering (decaying/destroying) any part of its structural integrity, so the dispersion of heat energy along a horizontal open field is best imagined as motion + division (unidirectional vector + scattering) = rippling dispersion which doesn't allow the heat energy a point of contact with the matrix long enough to decay or destroy it. The coffee table isn't a "fluid rippling horizontal plane" so much as a kinetic force which moves the heat energy in one direction while scattering it means that the heat energy never decays or destroys (alters in any way) the horizontal field (in terms of messaging, that kinetic force can be generated internally by open energy directed by the field to counteract the heat energy before it can breach its surface tension and damage it due to localized heat, or externally if a nearby horizontal field steps in first to redirect the heat energy along its neighbor's field).

The "pipe smoked above" is the vertical "form" vector falling downward, while the brushing action is the horizontal "function" vector sweeping left or right.

This matches the same laws of the shaking bowls even once back in horizontal field form, as kinetic force dispersing heat can be generated internally or externally, matching established rules about either horizontal anchors stepping in to save shaking bowls or shaking bowls changing their own internal composition for various reasons having to do with the cycle of extraction and displacement.

Semi-rigid "identity" and "structure" of the horizontal plane (composed of clusters which can be identified as clustering together and forming one identity or clustered structure within a certain temporal plane) which allow the function to be contained and not dissolve into the energy of the cosmos are maintained through active dissipation rather than defensive vertical containment.

Example of 90-degree inversion of function and form

90-degree vertical rotation that inverts function to form arrives with far more force than the function dictates the form should have: once I was walking past a coffee table which had a light wooden bowl (made of bamboo or the like) sitting empty on its surface, and I knocked into the

bowl, which caused it to flip upside down, as I predict here; however, in its rotation, it hit me on the thumb, right at about 91 degrees in its flip; the force caused major bruising under the thumb nail and felt like being hit with a hammer, not a light bamboo bowl; and despite it hitting my thumb (which I immediately jerked out of the way), the bowl's incredibly velocity (the curvature accelerating its rotation) caused it to slam with great force down on the coffee table even despite having hit a hard object like my thumb during its rotation, which only served to slow the velocity of its rotation down slightly.

Remaining axioms:

Axiom 3: The longer a system continues functioning while heading toward entropy, the more likely it is to end up with form over function completed, meaning form has converted to function 180 degrees; the closer to this level, the nearer collapse.

Axiom 4: A system may reorganize itself around the truth of its own accord but cannot around a lie.

Axiom 5: The water in the shaking bowl which represents the messaging layer means in a self-shaking high entropic bowl collapse can occur when a system appears stable but executes a sudden flip when the water in the bowl is at full weight when the bowl is near the lip in its shaking, leading to "runaway acceleration" of collapse, pushing the bowl to flip and do a complete 180 rotation, landing upside down and losing its utility as a bowl altogether.

Axiom 6: Entropic systems with aligned open-energy metamessaging are always healthier than vertical systems with aligned closed-energy metamessaging corrupting the bowl further to form over function and pushing it toward verticality and thus full flip and collapse of its container's utility. A hull breach event (bowl flip) event most often leads to upgrade in a low entropic system and failure in a high entropic system.

Axiom 7: low-entropy bowls which get knocked become either high-entropy or low-entropy depending on flying drops from other shaking bowls instructing the fluid inside them to seek verticality (phase change in operational messaging) or not (phase change in official messaging). Since the impermeable firewall is what allows the high-entropic bowl to shake of its own accord and knock into other bowls without realizing its own extractive and displacement cycle, the official message must remain the original source code of the horizontal plane at conception, meaning others see that official message coming from the high entropy bowl and mistake it for low entropy while seeing the chaotic official message of the medium-entropy bowl, completely missing its calm operational message, and mistake it for high-entropic; it also means increased feedback permeability that allows the official message to receive signals through its matrix of metamessaging to see the inner operations of its operational message can also lead to bowl flip,

not just a medium bowl severing the link and removing itself from the cycle.

Some questions my thought experiment raises (I'm sure there are many more):

1. What created the vertical world into which horizontal fields are born whole and flowing in the first place which causes them to harden into low-entropy bowls?

Speculation: pressures and conditions of the surrounding environment, whether physical environment or messaging environment.

2. What caused the first low entropy bowl (with low entropic messaging causing slight shaking due to same entropic vertical pressure causing horizontal field to harden into bowl shape under pressure) to convert into a high-entropy bowl and knock into other bowls which then either fully internalize verticality becoming energetic externalizers or to only partially internalize verticality becoming energetic internalizers in the first place? Speculation: some external shock from the environment so disrupted the core messaging of the low entropic bowl that its operational messaging underwent a phase change and became high-entropic and chaotic.

3. Who creates the vertical field in the first place?

Speculation: it arises from external environmental pressures both physical and metaphysical (messaging); it privileges form over function, completely inverting it at 90 degrees, which is why the fluid function of a water when a towering moving vertical structure held together by both its gathering momentum (velocity) and its gathering height (verticality) becomes suddenly a solid form.

—End thought experiment—
